Readings: Chapter 12

Selections

Projections

Nested loop joins

Sort-merge and hash joins

General joins and aggregates

Query processing

Some database operations are **EXPENSIVE**

Can greatly improve performance by being 'smart'

- e.g., can speed up 1,000,000x over naïve approach

Main weapons are:

1. clever implementation techniques for operators
2. exploiting 'equivalencies' of relational operators
3. using statistics and cost models to choose among these

A Really Bad Query Optimizer

For each Select-From-Where query block

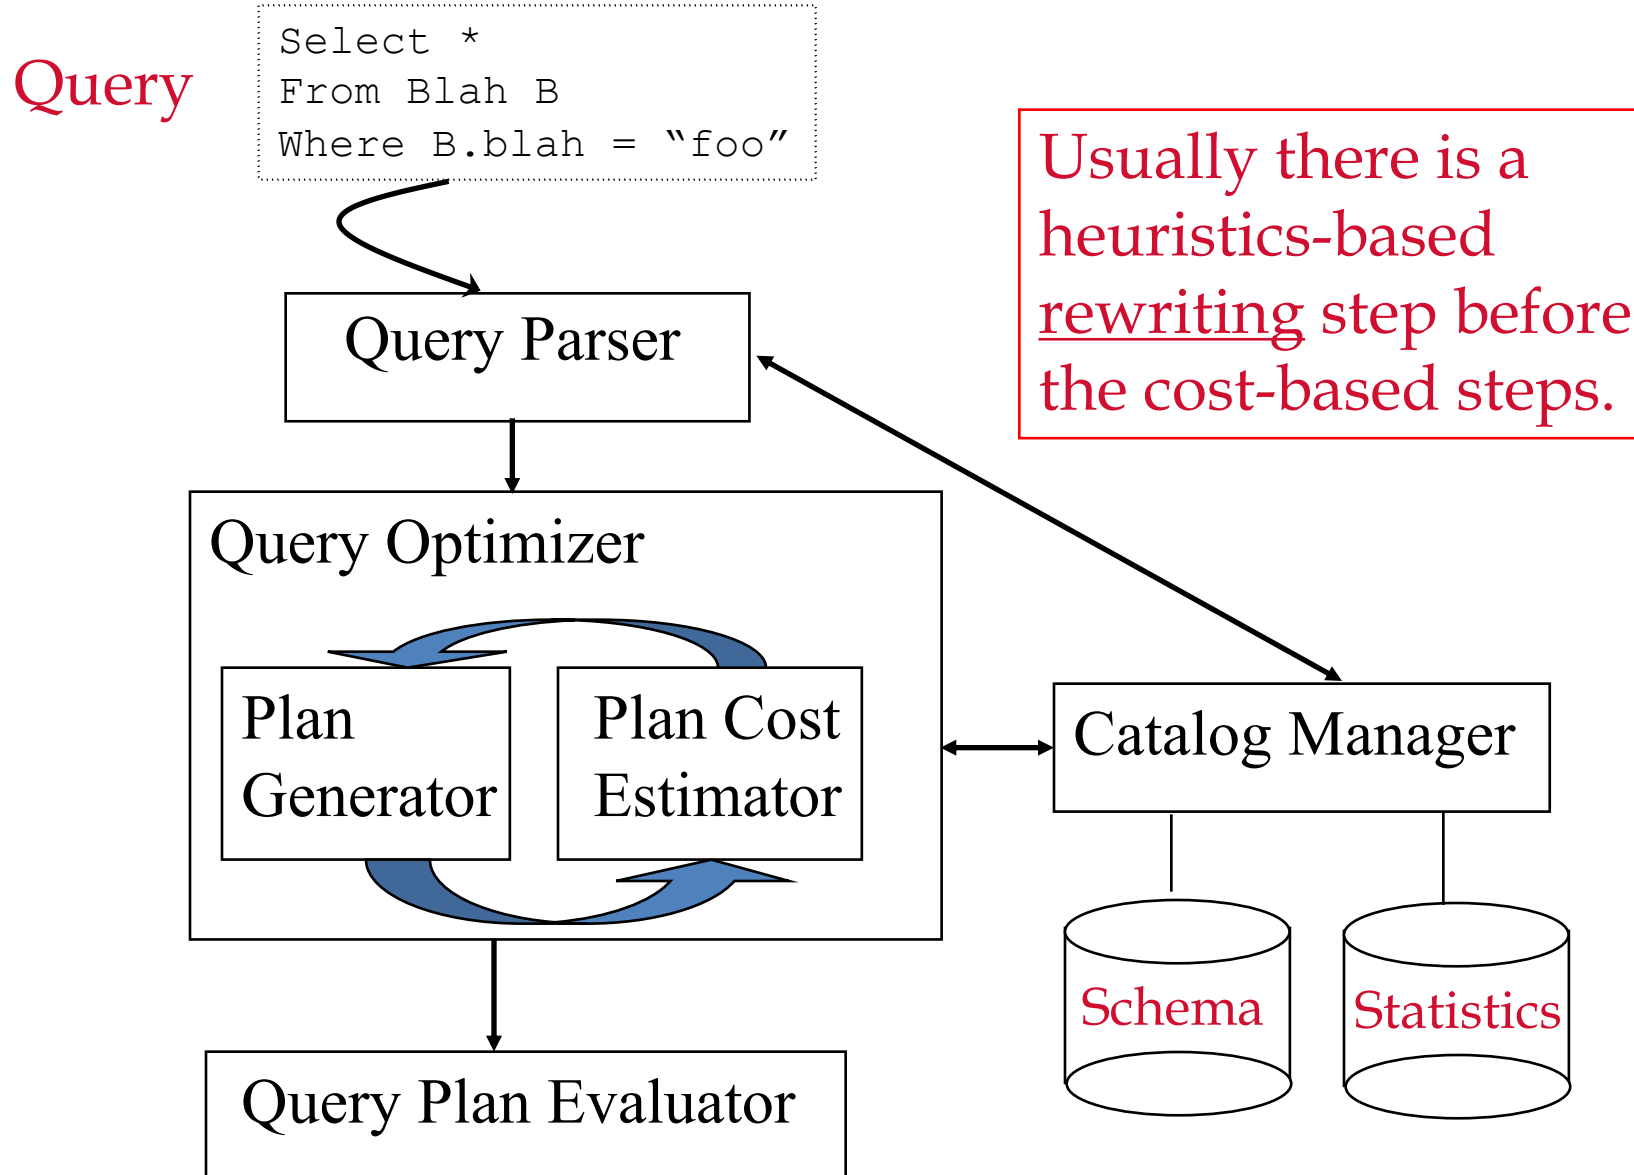

- Create a plan that:
 - Forms the Cartesian product of the FROM clause
 - Applies the WHERE clause
 - Incredibly inefficient
 - Huge intermediate results!

Then, as needed:

- Apply the GROUP BY clause
- Apply the HAVING clause
- Apply any projections and output expressions
- Apply duplicate elimination and/or ORDER BY

Query execution

The Query Optimization Game

‘Optimizer’ is a bit of a misnomer

Goal: pick a ‘good’ (i.e., low expected cost) plan

- Involves choosing access methods, physical operators, operator orders, ...
- Notion of cost is based on an abstract ‘cost model’

Roadmap for this topic:

- First: basic operators
- Then: joins
- After that: optimizing multiple operators

Relational Operations

We will consider how to implement:

- Selection (σ) Selects a subset of rows from relation
- Projection (π) Deletes unwanted columns from relation
- Join (\bowtie) Allows us to combine two relations
- Set-difference ($-$) Tuples in relation 1, but not in relation 2
- Union (\cup) Tuples in relation 1 and in relation 2
- Aggregation (SUM, MIN, etc.) and GROUP BY

Operators can be *composed* !

Next: *optimizing* queries by composing them

Schema for Examples

Sailors (*sid*: integer, *sname*: string, *rating*: integer, *age*: real)

Reserves (*sid*: integer, *bid*: integer, *day*: dates, *rname*: string)

Similar to old schema; *rname* added for variations.

Sailors:

- Each tuple is 50 bytes long, 80 tuples per page, 500 pages
- $N=500$, $p_S=80$

Reserves:

- Each tuple is 40 bytes long, 100 tuples per page, 1000 pages
- $M=1000$, $p_R=100$

Query Processing

Overview

Selections

Readings: Chapters 14.1-14.2

Projections

Nested loop joins

Sort-merge and hash joins

General joins and aggregates

Simple Selections

```
SELECT *  
FROM   Reserves R  
WHERE  R.rname < 'C%'
```

Of the form $\sigma_{R.attr \text{ op } value}(R)$

Question: how best to perform? Depends on:

- available indexes/access paths
- expected size of the result (# of tuples and/or # of pages)

Size of result approximated as

*size of R * reduction factor*

- “reduction factor” is usually called selectivity
- estimate of selectivity is based on statistics

Alternatives for Simple Selections

With no index, unsorted:

- Must essentially scan the whole relation
- cost is M (#pages in R); for “reserves” = 1000 I/Os

With no index, sorted:

- cost of binary search + number of pages containing results.
- For reserves = 10 I/Os + $\lceil \text{selectivity} * \# \text{pages} \rceil$

With an index on selection attribute:

1. Use index to find qualifying data entries,
 2. then retrieve corresponding data records
- Note: Hash index useful only for equality selections

Using an Index for Selections

Cost \sim #qualifying tuples, clustering

– Cost factors:

- find qualifying data entries (typically small)
- retrieve records (could be large w/o clustering)

– Our example, “reserves” relation:

if 10% of tuples qualify (100 pages, 10000 tuples)

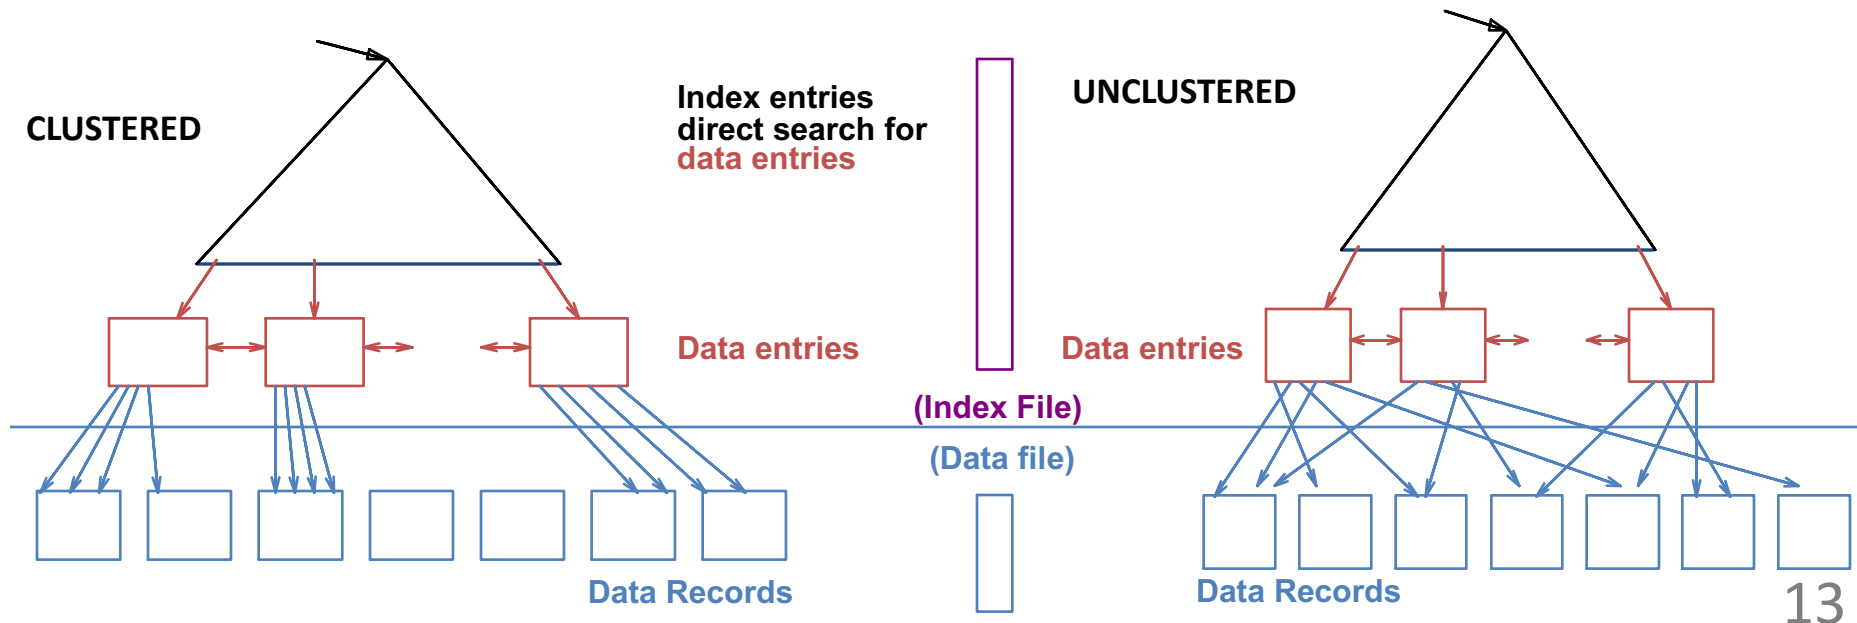

- *clustered* index \rightarrow a bit more than 100 I/Os
- *unclustered* \rightarrow could be up to 10000 I/Os!

unless...

Selections using Index

Important refinement for unclustered indexes:

1. Find qualifying data entries
2. Sort the rid's of the data records to be retrieved
3. Fetch rids in order
 - Ensuring that each data page is looked at just once

General Selection Conditions

☞ *(day < 8/9/94 AND rname = 'Paul') OR bid = 5 OR sid = 3*

First converted to conjunctive normal form (CNF)

– *(day < 8/9/94 OR bid = 5 OR sid = 3) AND (rname = 'Paul' OR bid = 5 OR sid = 3)*

We assume no ORs (conjunction of *<attr op value>*)

A **B-tree** index matches (a conjunction of) terms that involve only attributes in a *prefix* of the search key

– Index on *<a, b, c>* matches *a = 5 AND b = 3*, but not *b = 3*

Hash indexes must have all attributes in search key

Selections – 1st approach

1. Find the *cheapest access path*
2. Retrieve tuples using it
3. Apply the terms that don't **match** the index (if any):
 - *Cheapest access path*
An index or file scan with the fewest estimated page I/Os
 - **Terms that match** this index reduce the # of tuples *retrieved*
 - **Other terms** are used to discard some retrieved tuples, but do not affect number of tuples/pages fetched

Cheapest Access Path - Example

Consider *day < 8/9/94 AND bid=5 AND sid=3*

A **B+ tree index on day** can be used;

- then, *bid=5* and *sid=3* must be checked for each retrieved tuple

Similarly, a hash index on *<bid, sid>* could be used;

- Then, *day<8/9/94* must be checked

How about a B+tree on <rname, day>?

How about a B+tree on <day, rname>?

How about a Hash index on <day, rname>?

Selections – 2nd approach: Intersecting RIDs

If we have 2 or more matching indexes (w/Alt. (2) or (3) for data entries):

1. Get **sets of rids** of data records using **each** matching index
2. Then *intersect* these **sets of rids**
3. Retrieve the records and apply any remaining terms

EXAMPLE: Consider *day<8/9/94 AND bid=5 AND sid=3*

– With (i) a **B+ tree index on day** and (ii) an **index on sid**:

1. a) Retrieve rids of records satisfying *day<8/9/94* using the first
b) Retrieve rids of recs satisfying *sid=3* using the second
2. **Intersect**
3. Retrieve records and check *bid=5*

Selections: summary

Simple selections

- On sorted or unsorted data, with or without index

General selections

- Expressed in conjunctive normal form
- Retrieve tuples and then filter them through other conditions
- Intersect RIDs of matching tuples for non-clustered indexes

Choices depend on selectivities

Break: The Halloween Problem

Story from the early days of System R.

While testing the optimizer on 10/31/76(?), the following update was run:

```
UPDATE payroll  
SET salary = salary*1.1  
WHERE salary < 25K;
```

AND IT STOPPED WHEN ALL HAD salary \geq 25K!

Can you guess why? (hint: it was an optimizer bug...)

Query Processing

Overview

Selections

Projections

Readings: Chapter 14.3

Nested loop joins

Sort-merge and hash joins

General joins and aggregates

The Projection Operation

Issue is removing **duplicates**

```
SELECT  DISTINCT  
        R.sid, R.bid  
FROM    Reserves R
```

Basic approach is to use sorting

- **1.** Scan R, extract only the needed attributes (why do this first?)
- **2.** Sort the resulting set
- **3.** Remove adjacent duplicates
- Cost: Reserves with size ratio 0.25 = 250 pages
With 20 buffer pages can sort in 2 passes, so:
 $1000 + 250 + 2 * 2 * 250 + 250 = 2500$ I/Os

Projection: Can do better!

```
SELECT  DISTINCT  
        R.sid, R.bid  
FROM    Reserves R
```

Modify external sort algorithm (see chapter 13):

- Modify Pass 0 of external sort to eliminate unwanted fields
- Modify merging passes to eliminate duplicates
- Cost for above case:
read 1000 pages, write out 250 in runs of 40 pages,
merge runs = $1000 + 250 + 250 = 1500$

Projection Based on *Hashing*

Projection Based on *Hashing (explained)*

Partitioning phase:

- Read R using one input buffer
- For each tuple:
 - Discard unwanted fields
 - Apply hash function $h1$ to choose one of B-1 output buffers
- Result is B-1 partitions (of tuples with no unwanted fields)
 - 2 tuples from different partitions guaranteed to be distinct

Projection Based on *Hashing (explained)*

Duplicate elimination phase:

- For each partition
 - Read it and build an in-memory hash table
 - using hash function $h2$ ($\neq h1$) on all fields
 - while discarding duplicates
- If partition does not fit in memory
 - Apply hash-based projection algorithm recursively to this partition

Projection Based on *Hashing (explained)*

Cost ???

- Assuming partitions fit in memory
(i.e. #bufs \geq sqrt(#of pages))
- Read 1000 pages
- Write partitions of projected tuples (250 I/Os)
- Do duplicate elimination on each partition (total 250 I/Os)
- Total : 1500 I/Os

Discussion of Projection (1/2)

Sort-based approach is standard

- Better handling of **skew**, and result is **sorted**

If there are enough buffers, both have same I/O cost:

$$M + 2T$$

where:

- M is #pgs in R,
- T is #pgs of R with unneeded attributes removed

Although many systems don't use the specialized sort

Discussion of Projection (2/2)

If all wanted attributes are indexed

→ *index-only* scan

- Apply projection techniques to data entries (much smaller!)

If all wanted attributes are indexed as prefix of the search key

→ even better:

- Retrieve data entries in order (index-only scan)
- Discard unwanted fields
- Compare adjacent tuples to check for duplicates

Projections: summary

Projection based on *sorting*

Projection based on *hashing*

Can use *indexes* if they cover *relevant attributes*

Query Processing

Overview

Selections

Projections

Nested loop joins

Readings: Chapters 14.4-14.4.1

Sort-merge and hash joins

General joins and aggregates

Joins...

...are very common.

...can be very expensive (cross product in the worst case).

➔ Many approaches to reduce join cost!

Join techniques we will cover:

1. Nested-loops join
2. Index-nested loops join
3. Sort-merge join
4. Hash join

Equality Joins With One Join Column

```
SELECT *  
FROM   Reserves R1, Sailors S1  
WHERE  R1.sid=S1.sid
```

In algebra: $R \bowtie S$. Common! Must be carefully optimized. $R \times S$ is large; so, $R \times S$ followed by a selection is inefficient

Remember, join is associative and commutative

Assume:

- M pages in R, p_R tuples per page
- N pages in S, p_S tuples per page
- In our examples, R is Reserves and S is Sailors

We will consider more complex join conditions later

Cost metric : # of I/Os

We will ignore output costs

Simple Nested Loops Join

```
foreach tuple r in R do
    foreach tuple s in S do
        if  $r_i == s_j$  then add  $\langle r, s \rangle$  to result
```

For each tuple in the *outer* relation R, we scan the entire *inner* relation S

How much does this Cost?

$$(p_R * M) * N + M = 100 * 1000 * 500 + 1000 \text{ I/Os}$$

– At 10ms/IO, Total: ???

What if smaller relation (S) was outer?

What assumptions are being made here?

Q: What is cost if one relation can fit entirely in memory?

Page-Oriented Nested Loops Join

```
foreach page  $b_R$  in R do
  foreach page  $b_S$  in S do
    foreach tuple  $r$  in  $b_R$  do
      foreach tuple  $s$  in  $b_S$  do
        if  $r_i == s_j$  then add  $\langle r, s \rangle$  to result
```

For each **page** of R

- get each **page** of S
- write out matching pairs of tuples $\langle r, s \rangle$, where r is in R-page and S is in S-page

What is the cost of this approach?

$$M * N + M = 1000 * 500 + 1000$$

- If smaller relation (S) is outer, cost = $500 * 1000 + 500$

Index Nested Loops Join

```
foreach tuple r in R do
    foreach tuple s in S where  $r_i == s_j$  do
        add  $\langle r, s \rangle$  to result
```

If there is an index on the join column of one relation (say S), can make it the inner and exploit the index

– Cost: $M + (M * p_R) * \text{cost of finding matching S tuples}$

For each R tuple, cost of probing S index is about 1.2 for hash index, 2-4 for B+ tree. Cost of then finding S tuples (assuming Alt. (2) or (3) for data entries) depends on clustering

Clustered index: 1 I/O per page of matching S tuples

Unclustered: up to 1 I/O per matching S tuple

Examples of Index Nested Loops (1/2)

Hash-index (Alt. 2) on *sid* of Sailors (inner):

- Scan Reserves: 1000 page I/Os, 100×1000 tuples
- For each Reserves tuple:
 - 1.2 I/Os to get data entry in index,
 - plus 1 I/O to get (the exactly one) matching Sailors tuple

Examples of Index Nested Loops (2/2)

Hash-index (Alt. 2) on *sid* of Reserves (inner):

- Scan Sailors: 500 page I/Os, 80×500 tuples
- For each Sailors tuple:
 - 1.2 I/Os to find index page with data entries,
 - plus cost of retrieving matching Reserves tuples
 - Assuming uniform distribution, 2.5 reservations per sailor ($100,000 / 40,000$). Cost of retrieving them is 1 or 2.5 I/Os depending on whether the index is clustered

Block Nested Loops Join

Page-oriented NL doesn't exploit extra buffers

Alternative approach: Use one page as an input buffer for scanning the inner S, one page as the output buffer, and use all remaining pages to hold 'block' of outer R

For each matching tuple r in R-block, s in S-page, add $\langle r, s \rangle$ to result. Then read next R-block, scan S, etc

Examples of Block Nested Loops

Cost: Scan of outer + #outer blocks * scan of inner

- #outer blocks = $\lceil \# \text{ of pages of outer} / \text{blocksize} \rceil$

With Reserves (R) as outer, and 100 pages of R:

- Cost of scanning R is 1000 I/Os; a total of 10 *blocks*
- Per block of R, we scan Sailors (S); 10*500 I/Os

With 100-page block of Sailors as outer:

- Cost of scanning S is 500 I/Os; a total of 5 blocks
- Per block of S, we scan Reserves; 5*1000 I/Os

With sequential reads considered, analysis changes: may be best to divide buffers evenly between R and S

Nested loop joins: summary

Simple nested loops

- Optimized by page-oriented access

Index nested loops

- Costs depend on the type of index

Block nested loops

- Optimization of page nested loops which uses memory buffers

Query Processing

Overview

Selections

Projections

Nested loop joins

Sort-merge and hash joins

Readings: Chapters 14.4.2-14.4.3

General joins and aggregates

Sort-Merge Join ($R \bowtie_{i=j} S$)

Sort R and S on the join column, then scan them to do a 'merge' (on join column), and output result tuples

Useful if

- one or both inputs are already sorted on join attribute(s)
- output is required to be sorted on join attributes(s)

'Merge' phase can require some back tracking if duplicate values appear in join column

R is scanned once; each S group is scanned once per matching R tuple. Note: Multiple scans of an S group will probably find needed pages in buffer

Example of Sort-Merge Join

<u>sid</u>	sname	rating	age
22	dustin	7	45.0
28	yuppy	9	35.0
31	lubber	8	55.5
44	guppy	5	35.0
58	rusty	10	35.0

<u>sid</u>	<u>bid</u>	<u>day</u>	rname
28	103	12/4/96	guppy
28	103	11/3/96	yuppy
31	101	10/10/96	dustin
31	102	10/12/96	lubber
31	101	10/11/96	lubber
58	103	11/12/96	dustin

Cost: Sort R + Sort S + (M+N)

- The cost of scanning, M+N, could be M*N (very unlikely!)

With 35, 100 or 300 buffer pages, both Reserves and Sailors can be sorted in 2 passes; total join cost: $2 * \text{\#passes} * (M+N) + (M+N) = 7500$

(BNL cost: 2500 to 15000 I/Os)

Refinement of Sort-Merge Join

We can combine the merging phases in the *sorting* of R and S with the merging required for the join

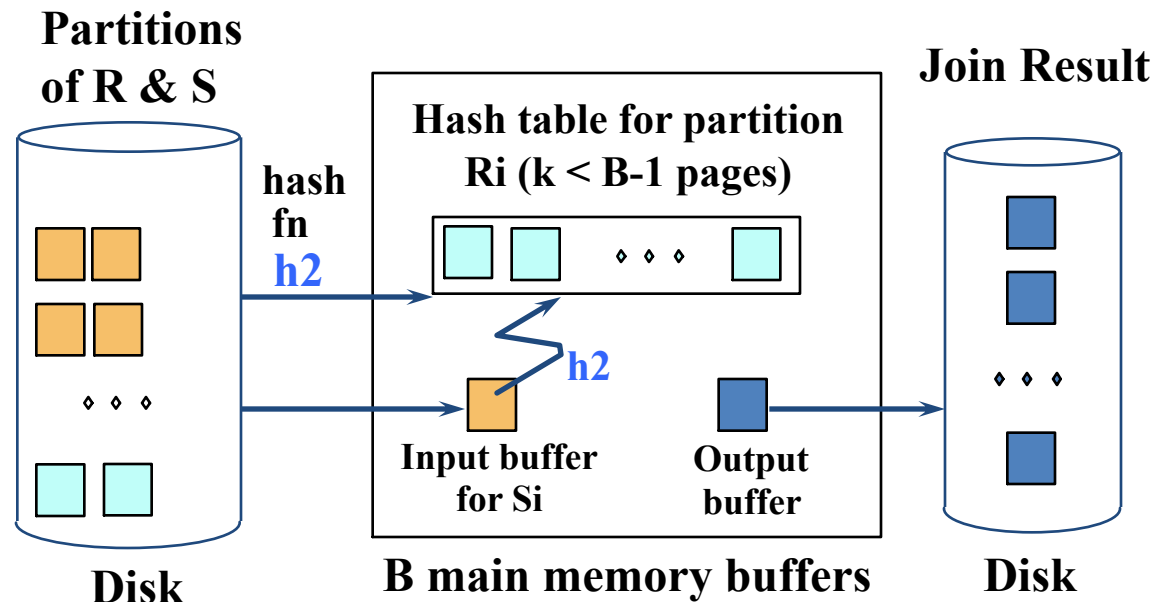

- Allocate 1 page per run of each relation, and ‘merge’ while checking the join condition
- With $B > \sqrt{L}$, where L is the size of the larger relation, using the sorting refinement that produces runs of length $2B$ in Pass 0, #runs of each relation is $< B/2$
- **Cost:** read+write each relation in Pass 0 + read each relation in (only) merging pass (+ writing of result tuples)
- In example, cost goes down from 7500 to 4500 I/Os

Hash-Join

Partition both relations using hash function h : R tuples in partition i will **only** match S tuples in partition i

Read in a partition of R , hash it using h_2 ($\neq h$). Scan matching partition of S , probe hash table for matches

Observations on Hash-Join

First pass creates $B-1$ partitions, each of size $S_i = N/(B-1)$

Need each $S_i \leq B-2$ in order to fit in memory for 2nd pass

→ Need $N/(B-1) \leq B-2$ \sqrt{N}
... or, roughly: $B >$
where N is size of smaller relation

More Observations on Hash-Join

Since we build an in-memory hash table to speed up the matching of tuples in the second phase, a little more memory is needed

If the hash function does not partition uniformly, one or more R partitions may not fit in memory. We can apply hash-join technique recursively to do the join of this R-partition with corresponding S-partition

Cost of Hash-Join

In partitioning phase, **read and write** both relations; $2(M+N)$

In matching phase, **read** both relations; $M+N$ I/Os

In our running example, this is a total of 4500 I/Os

Sort-Merge Join vs. Hash Join

Given a minimum amount of memory (*what is this, for each?*) both have a cost of $3(M+N)$ I/Os

Hash Join Pros:

- Superior if relation sizes differ greatly
- Shown to be highly parallelizable (*beyond scope of class*)

Sort-Merge Join Pros:

- Less sensitive to data skew
- Result is sorted (may help “upstream” operators)
- Goes faster if one or both inputs already sorted

Hash-Join

Let $B = 5$

Buckets:

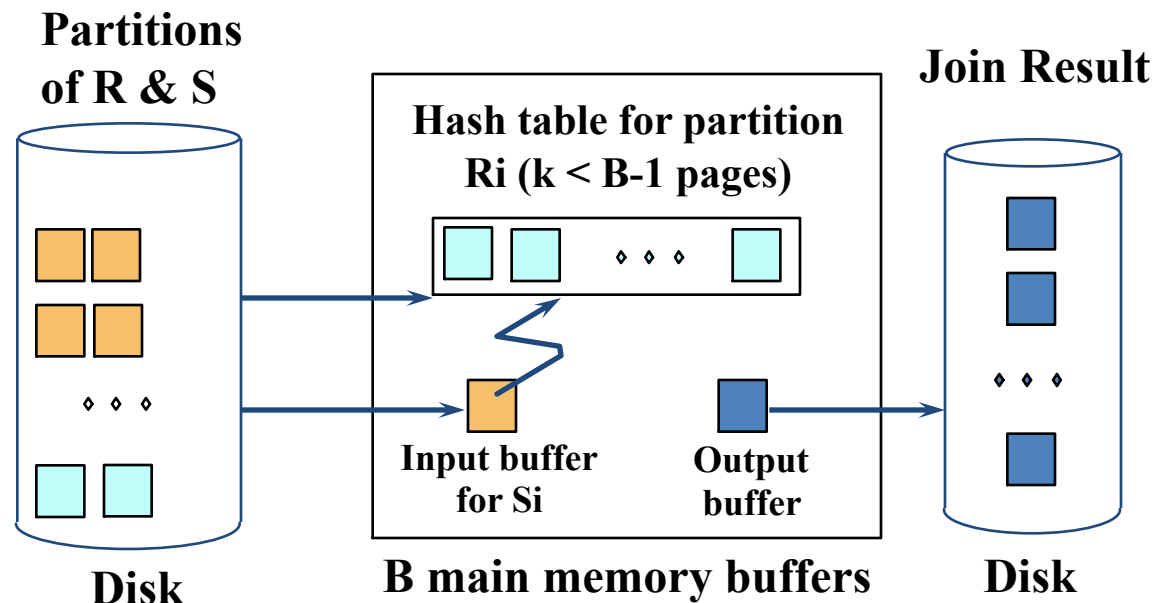

$b1: h \in [1,25]$

$b2: h \in [26,50]$

$b3: h \in [51,75]$

$b4: h \in [76,100]$

If $|F| \leq |M|$, in second phase build in-memory hash table on F partitions, and stream M partitions through memory

Summary

Sort merge join

- Relies on the sorted order of join attributes
- Produces sorted output

Hash join

- Uses little memory
- Great when one relations is much smaller than the other
- Has problems with data skew

Query Processing

Overview

Selections

Projections

Nested loop joins

Sort-merge and hash joins

General joins and aggregates

Readings: Chapters 14.4.5-14.7

General Join Conditions

Equalities over several attributes (e.g., *R.sid=S.sid* AND *R.rname=S.sname*):

- For Index NL, build index on *<sid, sname>* (if S is inner); or use existing indexes on *sid* or *sname*
- For Sort-Merge and Hash Join, sort/partition on combination of the two join columns

Inequality conditions (e.g., *R.rname < S.sname*):

- For Index NL, need (clustered!) B+ tree index
 - Range probes on inner; # matches likely to be much higher than for equality joins
- Hash Join, Sort Merge Join not applicable!
- Block NL quite likely to be the best join method here

Set Operations

Intersection and cross-product special cases of join

Union (Distinct) and Except similar; we'll do **union**:

Sorting based approach to union:

- Sort both relations (on combination of all attributes)
- Scan sorted relations and merge them
- *Alternative*: Merge runs from Pass 0 for *both* relations

Hash based approach to union:

- Partition R and S using hash function h
- For each S-partition, build in-memory hash table (using h_2), scan corresponding R-partition and add tuples to table while discarding duplicates

Aggregate Operations (AVG, MIN, etc.)

Without grouping:

- In general, requires scanning the relation
- Given index whose search key includes all attributes in the SELECT or WHERE clauses, can do index-only scan

Aggregate Operations (AVG, MIN, etc.)

With grouping:

- Sort on group-by attributes, then scan relation and compute aggregate for each group. Note: we can improve upon this by combining sorting and aggregate computation
- Similar approach based on hashing on group-by attributes
- Given tree index whose search key includes all attributes in SELECT, WHERE and GROUP BY clauses, we can do index-only scan
- If group-by attributes form prefix of the search key, we can retrieve data entries/tuples in group-by order

Impact of Buffering

If several operations are executing concurrently, estimating the number of available buffer pages is guesswork

Repeated access patterns interact with buffer replacement policy

- e.g., Inner relation is scanned repeatedly in Simple Nested Loop Join. With enough buffer pages to hold inner, replacement policy does not matter. Otherwise, MRU is best, LRU is worst (*sequential flooding*)
- Does replacement policy matter for Block Nested Loops?
- What about Index Nested Loops?

Summary

A virtue of relational DBMSs:

queries are composed of a few basic operators

- Implementation of operators can be carefully tuned
- Important to do this!

Many alternative implementations for each operator

- No universally superior technique for most operators

Must consider alternatives for each operation in a query and choose best one based on system statistics...

- Part of the broader task of optimizing a query composed of several operations
